ABSTRACT

The triangulation of planar domains is a relevant and largely studied problem in many applied sciences. This paper analyzes the computational time of a triangulation algorithm for plane domains with holes, introduced in a previous paper. This algorithm is based on the normal offsetting technique starting from a polygonal approximation of the domain boundary. It is shown that the computational time is linear with respect to the number of vertices of the triangulation. Experimental results confirm the theoretical upper bound obtained for the computational time.

1. Introduction

The generation of a high-quality grid of plane domains is fundamental in many areas of applied sciences, such as engineering and architecture. In [1], a grid generation and optimization framework is proposed, which automatically generates triangular grids over complex surfaces for architectural design. In [2] and [3], a new method based on Coulomb’s law is proposed with the same purposes. The construction of high-quality triangulations of plane domains is also fundamental for solving problems in many areas of applied mathematics [4, 5]. In fact, several numerical simulations are based on such triangulations and the quality of the results heavily depends on the quality of the triangulation [6, 7]. In particular, [8] proposes an algorithm generating a guaranteed quality mesh for the curvilinear triangulation of planar domains with piecewise polynomial boundary. In [9], we introduced a new triangulation algorithm named PolyFront (PF) based on polygon offsetting, starting from a polygonal approximation of the domain boundary. The constructed offset polygons are used to insert vertices and triangles, in particular, triangles are inserted subsequently to the current mesh as in the paving method [10, 11], and in the advancing front method [12-15]. In the same paper [9], we experimentally showed that this algorithm PF produces a good-quality mesh with reduced computational time. An interactive graphical user interface for PF was presented and illustrated in [16]. Moreover, the proposed method has been implemented in a software package including also the graphical user interface, that can be downloaded from https://docenti.unicam.it/public/Cad_2D.zip.

In this paper, we analyze the PF algorithm and we prove that the computational time of PF is $O(n_v \cdot n_e)$ when the domain has a polygonal boundary approximation made of $n_e$ edges and the generated triangulation has $n_v$ vertices.

The paper is organized as follows. The main proof is in Sections 2 and 3; in particular, in Section 2 we report and discuss the algorithm PF proposed in [9], for the reader’s convenience; in Section 3, we analyze the PF algorithm and theoretically estimate its computational cost. Then, in Section 4, we confirm by experiments the upper bound of the computational time. Finally, in Section 5, we give some final remarks and conclusions.

2. The Algorithm

For the reader’s convenience, we report PF, the triangulation algorithm proposed in [9], and we give the computational cost of some steps of PF. PF constructs a triangulation of a planar connected domain $\Omega \subset \mathbb{R}^2$ with holes, this construction starts from a polygonal approximation of the boundary $\partial \Omega$ of the domain. So, in the following $\Omega$ is supposed to have a polygonal boundary, otherwise, it is replaced by a domain having a boundary equal to a polygonal approximation of $\partial \Omega$. Moreover, the proposed algorithm constructs triangulations where the length of the triangle edges is as much as possible near a desired length $d$. The constructed triangulation is defined by $S$, the set of triangulation vertices, and $T$, the set of its triangles.

We begin with some notations. We denote with $n_{bv}$ the number of the triangulation vertices chosen in $\partial \Omega$. A simple polygon $P$ with $k \geq 3$ edges is represented by an ordered list of its vertices $P = (v_0, v_1, ..., v_{k-1})$. The interior of the polygon is denoted with $I(P)$. We associate to each edge $E$ of $P$ a positive real number $d_E$ that gives the distance between two consecutive triangulation vertices chosen on $E$, of course, $d_E$ is chosen as near as possible to the desired length $d$. Moreover, we denote with $L_E$ the length of $E$. If $\Omega \subset \mathbb{R}^2$ has $h$ holes, then it is represented by a list of polygons $(P^E, P^I_1, ..., P^I_h)$, where $\partial I(P^E)$ is the external boundary of $\Omega$ and $\partial I(P^I_i), i = 1, 2, ..., h$ are the boundaries of its $h$ holes. We note that with this representation we have $\Omega = I(P^E) \cup_{i=1}^{h} I(P^I_i)$, and so we use the following notation $\Omega = D(P^E, P^I_1, ..., P^I_h)$. Moreover, the vertices of a given polygon $P$ are ordered counterclockwise when $P$ is an external polygon and clockwise otherwise. In particular, when $\Omega$ has no hole ($h = 0$) then in its representation we have only the external polygon and so $\Omega = D(P^E)$. For example, Fig. (1a) shows a domain $\Omega$ with one hole, its representation is $\Omega = D(P^E, P^I_1)$ where the external polygon is $P^E = (v_0, ..., v_6)$ and the unique internal polygon is $P^I_1 = (u_0, ..., u_3)$. 

We define edge of $\Omega = D(P^E, P_1^I, ..., P_n^I)$ as an edge of a polygon in its representation. Let $n_e$ be the number of edges of $\Omega$ and let $E_j, j = 1, 2, ..., n_e$ its edges. The length of the boundary of $\Omega$ is given by $p_\Omega = \sum_{j=1}^{n_e} L_{E_j}$. We define subsequent domains of a given domain $\Omega$ the domains contained in $\Omega$ such that their edges are parallel to the edges of $\Omega$ and are at a fixed distance from them. Fig. (2a) shows the result obtained by using the construction of the subsequent domains starting from the domain $\Omega$ shown in Fig. (1a), in particular, the domain $\Omega = \Omega_0 = D((v_0, ..., v_6), (u_0, ..., u_3))$ has a unique subsequent domain $\Omega_1 = D((w_0, ..., w_6), (z_0, ..., z_3))$, the domain $\Omega_1$ has three subsequent domains $\Omega_2 = D((y_0, y_1, y_2))$, $\Omega_3 = D((x_0, x_1, x_2))$ and $\Omega_4 = D((t_0, ..., t_3))$, and these last three domains have no subsequent domain.

In the following, we report the $PF$ algorithm that has been proposed in [9] and computes a triangulation of a generic domain $\Omega \subset \mathbb{R}^2$. $PF$ uses the construction of the subsequent domains starting from a given domain $\Omega$ to compute a triangulation of the domain itself. In Fig. (2b) we have the resulting triangulation obtained on the domain shown in Fig. (1a) by using $PF$. 
Algorithm 1 (PF)

Let $\Omega \subset \mathbb{R}^2$ be a given domain, let $d$ be the desired length for a triangulation on $\Omega$; construct a triangulation on $\Omega$ by computing $\mathcal{S}$ and $\mathcal{T}$ as follows:

- **S1 Initialization**: $\Omega_0 = \Omega$, $i = 0$, $j = 0$, $\mathcal{S} = \emptyset$, $\mathcal{T} = \emptyset$.
- **S2 Insert in $\mathcal{S}$ the vertices chosen on $\partial \Omega$.
- **S3 Create the $h(i) \geq 0$ subsequent domains of $\Omega_i$; denote these domains with $\Omega_{i+1}, \Omega_{i+2}, \ldots, \Omega_{i+h(i)}$; set $j = j + h(i)$.
- **S4 Insert in $\mathcal{S}$ the vertices chosen on the boundary of the subsequent domains of $\Omega_i$.
- **S5 Insert in $\mathcal{T}$ the triangles obtained by triangulating the polygonal domain between $\Omega_i$ and its subsequent domains, if $h(i) = 0$ triangulate $\Omega_i$.
- **S6 Set $i = i + 1$ and if $i \leq j$ go to S3.
- **S7 Compute the mesh optimization.

**Figure 3**: The steps of the PF algorithm for domain $\Omega$ of Fig. (1a). (a) Step S3 for $i = 0$; (b) Step S4 for $i = 0$; (c) Step S5 for $i = 0$; (d) Step S3 for $i = 1$; (e) Step S4 for $i = 1$; (f) Step S5 for $i = 1$; (g) Step S5 for $i = 2$; (h) Step S5 for $i = 3$; (i) Step S5 for $i = 4$. 
In step S2 we insert in $S$ some points chosen on the boundary of $\Omega$ in the following way. For each edge $E$ of $\Omega$, we define $n_E$ as the largest integer such that $|L_E - n_E d| \leq \frac{d}{2}$ and we define $d_E = \frac{L_E}{n_E}$, then we insert, in $S$, $n_E + 1$ uniformly distributed points of $E$ such that two consecutive points have distance equal to $d_E$, note that for each edge $E$ we have:

$$\frac{d}{2} \leq d_E < \frac{3d}{2}.$$  \hspace{1cm} (1)

With this construction, we have that the number $n_{bv}$ of the triangulation vertices chosen in $\partial \Omega$ is

$$n_{bv} = \sum_{j=1}^{n_e} n_{E_j} = \sum_{j=1}^{n_e} \frac{L_{E_j}}{d_{E_j}}.$$  \hspace{1cm} (2)

The computational time necessary for this construction is $O(n_{bv})$, and the following inequalities hold

$$\frac{2p_B}{3d} \leq n_{bv} \leq \frac{2p_B}{d}.$$  \hspace{1cm} (3)

Fig. (1b) shows the $n_{bv}$ triangulation vertices chosen in $\partial \Omega$, note that two consecutive vertices chosen in an edge $E$ of $\partial \Omega$ have a fixed distance $d_E$ that is as near as possible to $d$.

In step S3, at the generic $i$-th iteration, we construct $\Omega_{i+1}, \Omega_{i+2}, \ldots, \Omega_{i+h(i)}$ the subsequent domains of $\Omega_i$ by using a parallel offsetting technique; these domains are further processed in the next iterations of the algorithm. This not trivial construction of the subsequent domains of a given domain $\Omega_i$ is carried on in such a way that each edge $E'$ of the subsequent domains of $\Omega_i$ is parallel to an edge $E$ of $\Omega_i$, is inside $\Omega_i$ and the distance between $E'$ and $E$ is $\frac{\sqrt{3}}{2}d_E$, that is the height of an equilateral triangle with edge length $d_E$. Moreover, we put $d_{E'} = d_E$. Figs. (2a, 3a, 3d), show similar examples of this construction, see [9] for more details. At each $i$-th iteration the computational time required for this construction is $O(n_i^2)$, in fact for each $i$ it depends quadratically on the number of edges of $\Omega_i$ that is $O(n_i)$.

In step S4, at the generic $i$-th iteration, we insert in $S$ some points chosen on the boundary of $\Omega_{i+1}, \Omega_{i+2}, \ldots, \Omega_{i+h(i)}$ the subsequent domains of $\Omega_i$. These points are chosen in such a way that, together with the triangulation vertices previously placed along the boundary of $\Omega_i$, they determine as many as possible equilateral triangles in the strip $\Omega_i \cup \cup_{i=h(i)+1}^{i+h(i)} \Omega_h$. In particular, when $E'$ is an edge of a subsequent domain of $\Omega_i$ parallel to edge $E$ of $\Omega_i$, we insert in $S$ points of $E'$ uniformly distributed that satisfy the following two properties: 1) the distance between two consecutive points is equal to $d_{E'} = d_E$; 2) at least one of these points is on the axis of the segment defined by two consecutive triangulation vertices of $E$ previously inserted in $S$. When necessary, we insert also the endpoints of $E'$. We note that when $\Omega_i$ has no subsequent domains, i.e. $h(i) = 0$, we do not insert other points in $S$. At each $i$-th iteration the computational time required for this construction is $O(n_{bv})$ in fact this is the order of the number of triangulation vertices chosen in the edges of the subsequent domains of $\Omega_i$. Once we inserted in $S$ the points corresponding to each subsequent domain of $\Omega_i$, we control if two of the inserted points are too close to each other, in this case, the points are modified. At each $i$-th iteration, this check can be made by cycling on the edges of $\Omega_i$ and the edges of its subsequent domains, and so its computational cost is $O(n_i^2)$. In Figs. (3b, 3e) some examples are shown.

In step S5, at the generic $i$-th iteration, we triangulate the strip $R_i = \Omega_i \cup \cup_{h=j+1}^{i+h(i)} \Omega_h$, between a domain $\Omega_i$ and its subsequent domains, by using the triangulation vertices inserted in step S4, see Figs. (3c) and (3f) as examples of the triangulation obtained with this step. Note that, if the domain $\Omega_i$ has no subsequent domains, i.e. $h(i) = 0$, we triangulate $\Omega_i$, see Figs. (3g, 3h, 3i) as examples of the triangulation obtained with this step when $h(i) = 0$. In particular, the triangulation of the strip $R_i$ is performed by two different phases: in the first phase we construct the equilateral triangles whose union gives a region $S_i \subset R_i$, every one of these equilateral triangles has at least one vertex on $\partial \Omega_i$ and at least one vertex on $\partial (\cup_{h=j+1}^{i+h(i)} \Omega_h)$; in the second phase, the Delaunay triangulation of each connected component of the critical region $R_i \setminus S_i$ is computed by using the Watson algorithm [17], possibly after having added a negligible number of Steiner points, depending on a certain closeness criterion.
Analysis of the Computational Cost of PolyFront

Egidi et al.

Figure 4: The first phase of step S5 of the PF algorithm for domain $\Omega$ of Fig. (1) inserts in $S$ only the equilateral triangles. The more dark areas are triangulated in the second phase.

For example, Fig. (4) shows the triangulation computed with the first phase on the strip $R_0 = \Omega_0 \setminus \Omega_1$ shown in Fig. (3b), moreover, the more dark areas denote the critical region $R_0 \setminus S_0$ where in the second phase of step S5 we use the Watson algorithm to triangulate such a region and in Fig. (3c) it is shown the final result. In Figs. (5) and (11), we have the triangles inserted in $T$ by using only the first phase of step S5 at each iteration $i$. Let $\Gamma$ be the union of all the critical regions $R_i \setminus S_i$ obtained at each iteration $i$-th of the PF algorithm, in Fig. (5) $\Gamma$ is the untriangulated part of the regular polygon, in Fig. (11) $\Gamma$ is the more dark area. We note that, in this region the PF algorithm at each $i$-th iteration applies the Watson algorithm on connected subdomains to compute the Delaunay triangulation of the triangulation vertices inside $\Gamma$. Moreover, at each $i$-th iteration the computational time required for the first phase of step S5 is $O(n_{bv})$ because it depends on the number of triangulation vertices of the triangulation chosen on the boundary of $\Omega_i$. The analysis of the computational cost of the second phase of step S5 will be made in Section 3.

Figure 5: The untriangulated part is the union of all the critical regions.

Step S6 allows the recursively application of steps from S3 to S5 to each of the domains arising from step S3; this process ends since at iteration $i$-th each subsequent domain of $\Omega_i$ is contained in $\Omega_i$. Moreover, by construction, the distance between each edge $E'$ of any subsequent domain of $\Omega_i$ and the parallel edge $E$ of $\Omega_i$ is equal to $\frac{\sqrt{3}}{2}d_E$ but $d_E > \frac{d}{2}$. So, since the distance between the boundary of $\Omega_i$ and the boundary of its subsequent domain is greater than $\frac{\sqrt{3}d}{4}$ after $l = O(n_{bv})$ iterations there is no other subsequent domain. So the number of iterations of steps S3-S5 performed by the algorithm is $l = O(n_{bv})$.

We remark that the quality of the triangulation produced by the above procedure is already good. However, we optionally apply a mesh optimization to improve it. In step S7, at the end of the iterations, the triangulation constructed in the previous steps is optimized with respect to the minimal angle criterion and the maximal angle criterion, see [9] for more details. In Fig. (2b) we have the mesh obtained after optimization over the domain of Fig. (1a). We note that the optimization process is needed only for the triangles whose vertices are in $\Gamma$. 
3. Computational Time

Let $\Omega$ be a domain with polygonal boundary, $n_e$ be the number of edges of $\Omega$, $n_v$ be the number of triangulation vertices generated by the PF algorithm, $I$ be the number of iterations of steps S3-S5, $n_{bv}$ be the number of triangulation vertices chosen by the PF algorithm on $\partial \Omega$, $I' = \bigcup_{i=1}^{I} (R_i \setminus S_i)$ be the union of the critical regions arising when we apply the PF algorithm on $\Omega$. Then the iteration for $i = 1, \ldots, I$ of steps S3-S5 with the exception of the second phase of step S5 gives the triangulation of $\Omega \setminus I'$, see Figs. (5) and (11) for examples.

**Theorem 1.** The computational time of the PF algorithm for constructing the triangulation of $\Omega \setminus I'$ is $O(n_en_v)$.

**Proof:** We note that the number $n_v$ of the vertices of the triangulation constructed with the PF algorithm is $n_v = O(n_{bv}^2)$. Hence, for each iteration $i = 1, \ldots, I$ the computational time of all the steps S3-S5 with the exception of the second phase of step S5 is $O(n_v^2) + O(n_{bv}) = O(n_v n_{bv})$, moreover, $I = O(n_{bv})$ so that the computational time necessary for the construction of the triangulation of $\Omega \setminus I'$, is $O(n_v n_{bv}^2) = O(n_v n_{bv})$.

The Delaunay triangulation of the remaining part $I'$ is computed in the second phase of step S5 by applying the Watson algorithm in each critical region separately, and so its computational time is less than $O(K \log K)$ where $K$ is the number of the triangulation vertices that are inside $I'$, in fact this is the computational time of the Watson algorithm applied in whole $I'$.

In the following we prove that $K = O(\sqrt{\frac{n_v}{\pi}})$, in particular, we prove an elementary lemma concerning the plane tessellation $T_d$ made up of equilateral triangles with edge length $d$, (Fig. 6). Then we give two lemma where we evaluate the number of the triangulation vertices in $I'$ when $\Omega$ is a regular polygon and when $\Omega$ is a general domain.

![Figure 6: The segment S meets at most 4(\sqrt{3}L_s/(3d) + 1) interiors of triangles in tessellation T_d.](image)

**Lemma 1.** Given any segment $S$ of length $L_s$, the number $N(S)$ of triangles of $T_d$ whose interiors meet $S$ satisfies the following inequality

$$N(S) \leq 4 \left( \frac{L_s}{d} + 1 \right), \quad (4)$$

and the union of these $N(S)$ triangles is a polygonal disk with $N(S) + 2$ vertices.

**Proof:** Let $u_1 = (1/2, -\sqrt{3}/2)$, $u_2 = (1, 0)$, and $u_3 = (1/2, \sqrt{3}/2)$ unit vectors parallel to the edges of $T_d$ and $0 \leq \theta_i \leq \pi/2$ be the angle between $S$ and the direction determined by $u_i$. Up to symmetries of $T_d$, we can assume $\theta_1 \leq \theta_2 \leq \theta_3$ (cf. Fig. 6). Then, we have $\theta_1 \leq \pi/6 \leq \theta_2 \leq \pi/3 \leq \theta_3$.

We denote by $Q$ the smallest parallelogram among the ones which contain $S$, are unions of triangles of $T_d$, and have edges parallel to $u_2$ and $u_3$ (cf. Fig. 7). We think of $Q$ as the union of $L_2$ strips parallel to $u_3$ made up of triangles of $T_d$, where $dL_2$ is the length of the edges of $Q$ parallel to $u_2$. 

56
Because of the assumptions made on the \( \theta_i \)'s, \( S \) can meet at most two triangle interiors inside each strip, note that the union of these triangles gives a polygonal disk with \( N(S) + 2 \) vertices. Hence, we have \( N(S) \leq 2L_2 \) but \( dL_2 \leq (L_3/ \cos \theta_2 + 2d) \leq (2L_3 + 2d) \) so \( N(S) \leq 4(L_3/d + 1) \).

Now, we use the previous lemma in order to obtain the claimed upper bound on the number of triangulation vertices in \( \Gamma \) which arise when we perform the PF algorithm on a regular polygon.

**Lemma 2.** The union \( \Gamma \) of all the critical regions arising when we perform the PF algorithm on a regular polygon \( \Omega \), with \( n_e \) edges of length \( n \cdot d \), to get a triangulation with preferred edge length \( d \), has at most \( 4n_{bv}n_e/5 + 8n_e \) triangulation vertices, where \( n_{bv} = n_e \cdot n \) is the number of triangulation vertices on the boundary of the regular polygon.

**Proof:** It suffices to prove that inside each triangle \( T \) bounded by an edge of the polygon and two radii of its circumcircle, there are at most \( 4n_{bv}/5 + 8 \) triangulation vertices of the critical regions. Looking at \( T \) and denoting by \( R \) one of its radial edges, we see that the number of such triangulation vertices inside \( T \) is at most \( N(R) + 4 \), where \( N(R) \) is the number of triangles of the tessellation whose interiors meet \( R \) (cf. Fig. 8). In fact, by Lemma 1 the union of the triangles whose interiors meet \( R \) is a polygonal disk with \( N(R) + 2 \) vertices, but at most half of them plus one lies inside \( T \). Then, \( N(R) + 4 \) is obtained by considering the contribute of the other radial edge of \( T \).

Now, by Lemma 1 and taking into account that \( n_e \geq 3 \) and \( \sin x \geq \frac{3\sqrt{3}x}{2\pi} \) when \( 0 \leq x \leq \frac{\pi}{3} \), we have the inequalities

\[
N(R) \leq 4 \left( \frac{n}{2\sin(\pi/n_e)} + 1 \right) \leq 4 \left( \frac{n}{3\sqrt{3}/n_e} + 1 \right) \leq \frac{4n_{ne}}{5} + 4,
\]

which complete the proof.

**Figure 7:** The smallest parallelogram \( Q \) containing \( S \).

**Figure 8:** The triangulation vertices of the critical regions inside the triangle \( T \).

**Lemma 3.** Let \( \Omega \subset \mathbb{R}^2 \) be a domain with polygonal boundary \( \partial \Omega \). Let \( n_e \) be the number of its edges and let \( n_{bv} \) be the number of triangulation vertices chosen on \( \partial \Omega \). The union \( \Gamma \) of all the critical regions arising when we perform the PF algorithm on \( \Omega \) to get a triangulation with desired edge length \( d \), has at most \( 6n_{bv}n_e + 12n_e^2 - 16n_e \) triangulation vertices.

**Proof:** Let \( E_j, j = 1, \ldots, n_e \) be the edges of \( \Omega \). Let \( \Omega_i, i = 0, \ldots, I \), be the domains constructed in the PF algorithm. For \( i = 0, \ldots, I \), let \( E \) be an edge of domain \( \Omega_i \) and let \( E_1, \ldots, E_L \) be the edges of the subsequent domains of \( \Omega_i \) that are parallel to \( E \) and have distance \( \frac{\sqrt{3}}{2}d_e \) from \( E \). Then there exist \( L + 1 \) unique segments \( S_1, \ldots, S_{L+1} \) that join end points of \( E_1, \ldots, E_L \) and \( E \) such that \( (U_{i=1}^L E_i) \cup (U_{i=1}^{L+1} S_i) \cup E \) is a quadrilateral (cf. Fig. 9).

We denote with \( \mathcal{F} \) the set whose elements are either the segments above defined or edges of \( \Omega_i, i = 0, ..., I \). In Fig. (10) we can see an example of the set \( \mathcal{F} \). By using the PF algorithm in the domain \( \Omega_i \), we can identify \( n_e \) connected regions \( T_j, j = 1, ..., n_e \) (an example is shown in Fig. (11) characterized by the following properties.

\begin{itemize}
  \item \( T_j \) contains the regions where with the PF algorithm we have inserted equilateral triangles that come from edge \( E_j \) of \( \partial \Omega \), these triangles give a tessellation \( T_j \) made up of equilateral triangles with edge length \( d_{E_j} \).
  \item The triangulation \( T \), resulting from applying the PF algorithm without the smoothing step, is the union of \( T_j, j = 1, ..., n_e \), and of the triangulation of the vertices in \( \Gamma \).
  \item \( T_j \) has polygonal boundary whose edges are union of segments belonging to \( \mathcal{F} \).
  \item The edges of \( T_j \) are \( E_j \) and other \( k_j \) edges \( E^k_j, k = 1, ..., k_j \), moreover by construction we have
    \[
    \sum_{k=1}^{k_j} L_{E^k_j} \leq \rho_{\Omega}.
    \] (5)
\end{itemize}
First of all, we note that
\[ k_j \leq 3n_v - 4, \] (6)

that is a consequence of the following facts. For each \( k \neq j \), \( T_k \cap T_j \) is a graph with at most two edges, in fact \( T_k \cap T_j \) is the union of segments of \( F \) that are all aligned with eventually the exception of one segment. So that \( T_j \) has at most \( 2(n_v - 1) \) edges in common with the other \( n_v - 1 \) regions \( T_k, k \neq j \), and these edges are joined by at most \( n_v - 2 \) segments in \( F \).

By construction, each triangulation vertex in \( \Gamma \) belongs to a region \( T_j, j = 1, ..., n_v \). So to prove the lemma it suffices to see that inside each region \( T_j, j = 1, ..., n_v \) there are at most \( 6n_{bv} + 12n_v - 16 \) triangulation vertices inside \( \Gamma \). Looking at \( T_j \) we see that each vertex inside \( \Gamma \cap T_j \) is a vertex of a triangle in \( T_j \) whose interior meets \( E^k_j \) for some \( k = 1, ..., k_j \).

Moreover, for each \( k \) we have at most \( N(E^k_j) \) triangles of tessellation \( T_j \) whose interiors meet \( E^k_j \), and the union of these triangles is a polygonal disk with at most \( N(E^k_j) + 2 \) triangulation vertices, so that at most half of them plus one lies inside \( T_j \). Then inside \( T_j \) there are at most \( \sum_{k=1}^{k_j} \left( \frac{N(E^k_j)}{2} + 2 \right) \) triangulation vertices chosen in \( \Gamma \).

Now, by Lemma 1 and equations (1), (3), (5) we have the inequalities
\[
\sum_{k=1}^{k_j} \left( \frac{N(E^k_j)}{2} + 2 \right) \leq \sum_{k=1}^{k_j} \left( \frac{L_{E^k_j} + 1}{2} + 1 \right) + 2k_j \leq 2 \left( \frac{p_a}{a_{E^k_j}} + k_j \right) + 2k_j \leq 6n_{bv} + 4k_j,
\]

which, with (6), completes the proof. \( \square \)

**Theorem 2.** For domains with polygonal boundary approximation having \( n_v \) edges, the computational time of the PF algorithm is \( O(n_v n_p) \).

**Proof:** By Theorem 1, the computational time of steps S1-S6 is \( O(n_v n_p) + O(K \log K) \) where \( K \) is the number of triangulation vertices in \( \Gamma \). By Lemma 2 when the domain is a regular polygon and by Lemma 3, when the domain is a general domain with a polygonal boundary approximation with \( n_v \) edges, we have that \( K = O(n_v n_{bv}) \). Then, from the quite trivial fact that \( n_v = O(n_v^2) \) we have that the computational time of steps S1-S6 is \( O(n_v n_{bv}) \). Moreover, the optimization of the resulting mesh can be performed by cycling on the \( K \) triangulation vertices in \( \Gamma \), and so its computational cost is \( O(n_v n_{bv}) \).

We remark that in the worst case \( n_v = n_{bv} \) the computational cost of PF is \( O(n_v^{3/2}) \), instead in the more frequent case \( n_v << n_{bv} \) the computational cost of PF is \( O(n_v) \).

**4. Experimental Results**

In the experimental results, only the computational cost of the mesh construction without optimization has been considered, for two reasons: 1) the news of the PF algorithm is in the mesh construction; 2) even if the optimization is only needed on triangles lying on \( \Gamma \) and therefore its computational cost is \( O(n_v n_{bv}) \), in the present version of the optimization is made on all triangles. Tests have been performed on a Pentium 4 CPU 2.66GHz, RAM 480 Mb.

The three domains shown in Fig. (12) have been considered in the numerical simulations: \( \Omega^{(1)} \) is a polygon with 6 edges and without holes; \( \Omega^{(2)} \) has two holes and 14 edges; \( \Omega^{(3)} \) is a domain with one hole and curved boundary, the polygonal discretization of its boundary has 55 edges of which 12 are edges of the hole. In Fig. (13) we can see examples of mesh generated by the PF algorithm on these domains, larger meshes generated by PF have the same
aspect.

**Figure 12:** $\Omega^{(1)}$ is a polygon with 6 edges and without a hole; $\Omega^{(2)}$ has two holes and 14 edges; $\Omega^{(3)}$ has one hole and curved boundary whose discretization has 55 edges.

**Figure 13:** Mesh generated by PF on $\Omega^{(1)}$ has $n_v = 571$ vertices. Mesh generated by PF on $\Omega^{(2)}$ has $n_v = 650$. Mesh generated by PF on $\Omega^{(3)}$ has $n_v = 788$.

**Table 1:** Computational time $t$, in seconds [s], needed for mesh generation with the algorithm PF without optimization for the domain $\Omega^{(1)}$, shown in Fig. (12); $n_e = 6$ is the number of edges of the domain boundary, and $n_v$ is the number of vertices of the mesh constructed by PF. Also the value of $\frac{t}{n_en_v}$ is reported.

In Tables 1-3 we report the computational time $t$, in seconds [s], needed for the mesh generation with the PF algorithm without optimization for each of the domains $\Omega^{(i)}$, $i = 1,2,3$, shown in Fig. (12), for different values of the number of vertices $n_v$. In the same tables also the values of $\frac{t}{n_e n_p}$ are reported. For each domain $\Omega^{(i)}$, $i = 1,2,3$, in Fig. (14) there are reported the values of $n_v$ and of $\frac{t}{n_e n_p}$ on the $x$-axes and the $y$-axes, respectively. In addition, in Fig. (15) we reported the values of $n_v$ and of $t$ on the $x$-axes and the $y$-axes, respectively.

**Table 2:** Computational time $t$, in seconds [s], needed for mesh generation with the algorithm PF without optimization for the domain $\Omega^{(2)}$, shown in Fig. (12); $n_e = 14$ is the number of edges of the domain boundary, and $n_v$ is the number of vertices of the mesh constructed by PF. Also the value of $\frac{t}{n_e n_p}$ is reported.

From Tables 1-3 and Fig. (14) we can see that $\frac{t}{n_e n_p}$ is near constant. In addition, from Tables 1-3 and Fig. (15) we can conclude that $t = O(n_v)$. We note that in the considered domains $n_e << n_{b,v}$. 
Figure 14: In the x-axis there are displayed the values of $n_v$ and in the y-axis there are displayed the values of $\frac{t}{n_v n_e}$ obtained by using PF to generate a mesh on domains $\Omega^{(i)}$, $i = 1, 2, 3$. 
Analysis of the Computational Cost of PolyFront

**Figure 15:** In the x-axis there are displayed the values of \( n_v \) and in the y-axis there are displayed the values of \( t \) obtained by using \( PF \) to generate a mesh on domains \( \Omega^{(i)} \), \( i = 1, 2, 3 \).

## 5. Final Remarks

In this work, we analyze the computational time of \( PF \), that is a triangulation algorithm for 2D domains with holes. It is based on polygon offsetting starting from the domain boundary. In Theorem 2, we have shown that \( PF \) requires a computational time of \( O(n_v n_b) \). In particular, it is linear with respect to the number of the triangulation vertices \( n_v \), when \( n_v \), the number of the edges of the domain boundary approximation, is much smaller than \( n_b \), the number of vertices of the triangulation chosen in domain boundary, because \( n_v = O(n_b^2) \). Note that this situation is the most common one, even if the domain has a curved boundary, and experimental results confirmed the upper bound \( O(n_e n_v) \).

We remark that the proof of Theorem 2 is essentially based on the fact that the critical regions are concentrated near to a finite graph. This seems to be supported by the experimental results. Moreover, Lemma 2 gives an upper bound for the number of triangulation vertices of the union of all critical regions. Actually, the \( PF \) algorithm applies the Delaunay method to each critical region separately. This argument does not allow us to improve the theoretical upper bound of Theorem 2, but in practice reduces the computational time of the \( PF \) algorithm as it results from experiments.

This study of the computational time of \( PF \), together with the goodness of the generated mesh quality shown in [9], suggests that \( PF \) should be developed towards nonuniform meshes or a three-dimensional version of the proposed method.

## Conflict of Interest

The authors declare no potential conflict of interest.

## Acknowledgments

We would like to show our gratitude to University of Camerino, and in particular to Roberto Pennesi and Paolo Mancinelli for the technical support provided.
